(54) **Process for the polymerisation of ethylene obtained by cracking**

(57) An integrated process for the cracking of a feedstock to produce ethylene and the subsequent polymerization or oligomerization of the ethylene, in the ethane/ethylene stream, without passing through an ethane splitter comprising in cooperating arrangement the steps of:

- feeding a feedstock to a cracker operated at a maximum allowable tube wall temperature of from 1050°C to 1600°C;
- passing the resulting product through a separation step to remove hydrocarbon streams

- having a carbon content of 3 and greater;
- subjecting the resulting stream to a treatment to convert acetylene to ethylene;
- removing the methane and hydrogen from the resulting stream to produce a product having an ethylene content from 75 weight% to 95 weight%;
- feeding the resulting stream to a polymerization or oligomerization process and polymerizing or oligomerizing the ethylene; and
- separating the unpolymerized stream from the polymer and solvent, returning it to the cracker.

EP 1 001 001 A1

Description

[0001] The present invention relates to an integrated high temperature hydrocarbon cracking and olefin polymerization or oligomerization process. More particularly the present invention relates to an integrated process for preparing polyethylene and/or alpha-olefins from hydrocarbon feedstocks by high temperature cracking the hydrocarbon feedstocks, separating the C_2 fraction from the cracked gas into a feed comprising at least 75 weight % ethylene for polymerization or oligomerization. The advantages of this invention over the conventional method of cracking hydrocarbons, producing ethylene and polymerizing/oligomerizing the ethylene include: smaller load for the furnace, smaller cracked gas compressor, smaller acetylene processing unit, the absence of an ethane/ethylene splitter, a greatly reduced recycle of ethane, lower energy requirements, lower capital investment, lower operating costs and the possibility of packaging a small integrated ethylene/polyethylene or ethylene/alpha olefins plant.

[0002] At the Tenth Ethylene Forum, May 10-12, 1995, Stone and Webster presented a paper on the concept of an integrated ethylene plant and one or more down stream chemical plants to react dilute ethylene or propylene to produce a product such as polyethylene or polypropylene and the unreacted stream of dilute ethylene or propylene would then be recycled back to the ethane cracker. The benefit from the concept was twofold:

- a reduction in the capital cost and operating cost of the ethylene unit.
- a simple and cost effective way of debottlenecking existing ethylene units especially if already coupled to solution phase polyethylene units such as NOVA's SCLAIRTECH process. However, the paper failed to disclose high temperature ethylene furnaces or reactor materials to achieve high temperatures such as ceramic tubes or ceramic reactors.

[0003] In addition to the Stone and Webster paper, U.S. patent 5,430,211 issued July 4, 1995 assigned to the Dow Chemical Company teaches the use of dilute ethylene produced using catalytic cracking to produce ethyl benzene. The patent is restricted to the use of catalytically dehydrogenated dilute ethylene.

[0004] U.S. patent 5,488,148 issued January 30, 1996 assigned to the Vista Chemical Company claims the use of dilute ethylene in making sulfonated alkyl compounds.

[0005] Chapter 17, "Steamless Pyrolysis of Ethane to Ethylene" by Y. Sony, L.T. Velenyi, A.A. Leff, W.R. Kliwer and J.E. Metcalf (in the text Novel Production Methods for Ethylene, Light Hydrocarbons and Aromatics edited by L.F. Albright et al, Marcel Decker, Inc. N.Y. (1992)), teaches the high temperature cracking of ethane in ceramic furnace tubes, preferably silicon carbide at high temperatures.

[0006] None of the above art teaches an integrated high temperature cracking process to produce a 75 weight % ethylene feedstock integrated with a polymerization and/or oligomerization process or both together in parallel trains. Alpha olefins from oligomerization could be used directly as comonomers for polyethylene production.

[0007] The present invention provides an integrated process for the cracking of a feedstock to produce an ethylene rich stream and the subsequent polymerization or oligomerization of the ethylene stream without passing through an ethane/ethylene splitter comprising in cooperating arrangement the steps of:

- i) feeding a feedstock to a cracker operated at a maximum allowable tube wall temperature of from 1050°C to 1600°C;
- ii) passing the resulting product through a separation step to remove hydrocarbon streams having a carbon content of 3 and greater;
- iii) subjecting the resulting stream to a treatment to convert acetylene to ethylene;
- iv) removing the methane and hydrogen from the resulting stream to produce a product having an ethylene content from 75 weight % or more;
- v) feeding the resulting stream to a polymerization or oligomerization process which has an inherent high ethylene conversion per pass (i.e. greater than 85%) and can operate effectively at feed ethylene concentrations as low as 75 weight %, and polymerizing or oligomerizing the ethylene; and
- vi) separating the unpolymerized stream from the polymer and solvent, and returning it to the ethylene unit.

[0008] Figure 1 is a comparison of the mass balance in a conventional process and the process of the present invention.

[0009] Figure 2 is a comparison of the heat balance in a conventional process and the process of the present invention.

[0010] As used herein the term maximum allowable tube wall temperature refers to the maximum temperature of the external surface of an ethylene furnace tube or coil exposed to the heating section of the cracker. Although we refer to tube or coil, other physical arrangements of the reaction chamber are possible.

[0011] The feedstocks for use in the present invention are well known to those of ordinary skill in the art. For example,

feedstocks for use in accordance with the present invention include, but are not limited to, C₂₋₆ alkanes such as ethane, propane, butane, naphtha, raffinate, atmospheric gas oil, vacuum gas oil, distillate, crude oil, crude resids and mixtures thereof, etc.

[0012] The present invention employs a high temperature cracking process which produces a cracked gas containing hydrogen, methane, C₂ hydrocarbons, C₃ hydrocarbons and heavier constituents.

[0013] The steam cracking process and other cracking processes are well known to those skilled in the art. Steam cracking processes are generally carried out in radiant furnace reactors at elevated temperatures for short residence times, at low reactant partial pressures, high gas velocity, and a low pressure drop through the reaction zone. Any of the furnace designs known to those skilled in the art may be employed in the practice of the present invention.

[0014] However, the coils or tubes of the reactors should be adapted to have a high maximum allowable tube wall temperature. This refers to the outer surface of the tube or coil. In one preferred embodiment the maximum allowable tube wall temperature may range from 1050°C to 1400°C, depending on the material used and the operating severity (required conversion). For conventional HP alloys certain treatment helps to increase the tube life or reduce coking characteristics to permit a reasonable run length. For example, in the website "westaim.com" a tube or coil having an internal coating is described as Engineered Surface Coating by a company called WESTAIM. Typically, the metal beneath the coating comprises from about 23 to 35, preferably from 24 to 35 weight % of chromium. The metal may further comprise from 25 to 50, preferably from 30 to 45 weight % of nickel (Ni); from 1 to 3, preferably from 1.5 to 2.5 weight % of manganese (Mn); from 1 to 2, preferably from 1.5 to 2 weight % of silica (Si). The balance of the steel composition will be predominantly iron with other trace amounts (e.g. for elements other than carbon, typically less than 1 weight %, preferably from 0.1 to 1.0 weight %) of elements such as carbon, titanium, and tungsten, as is well known in the metallurgy arts.

[0015] Such austenitic steel tubes or coils may be used at maximum tube wall temperature from about 1050°C to 1250°C and preferably from 1050°C to 1150°C. At a temperature of 1050°C to 1250°C the conversion of the feedstock will result in about 75%-85% ethylene in the stream fed to the polymerization reaction in the absence of an ethane/ethylene splitter. At temperatures of about 1050°C to 1150°C, the conversion will result in about 75%-80% ethylene in the stream.

[0016] In a preferred embodiment of the invention, the tube or coil is ceramic. These tubes may be used at maximum allowable tube wall temperatures of about 1200°C to 1600°C. High temperature alloy tubes or coils may also be used at this temperature.

[0017] The ceramic may be silicon carbide in which case the maximum allowable tube wall temperature may be from about 1200°C to 1400°C, preferably from about 1200°C to 1350°C. At tube wall temperatures of 1200°C to 1350°C, a cracked gas stream is produced which contains ethylene in the mixed feed to the polymerization reactor which may range from about 80-97, preferably 90-97 weight %.

[0018] The hydrocarbon feed to the steam cracker is typically in vapor phase or it may comprise a mixed liquid-vapor phase. The most preferred feedstocks for steam cracking are C₂₋₄ alkanes, naphtha, and mixtures thereof.

[0019] Generally, preheated feed is introduced into a convection zone of a pyrolysis furnace to further preheat the feed to a temperature below that at which significant reaction takes place (e.g., 400°C to 640°C).

[0020] Typically small amounts of steam are added to the feed prior to introduction to the radiant reaction zone of the pyrolysis furnace to provide a weight ratio of from about 0.1 to 2 parts of steam to hydrocarbon, preferably from about 0.1 to 1 (based on the weight of the feed). The steam assists vaporization of the feed and reduces the hydrocarbon partial pressure in the reaction zone in order to improve olefin yields. The feed in process tubes or coils is then cracked at maximum tube wall temperature up to about 1400°C.

[0021] Typically operating conditions comprise an inlet temperature to the radiant heating section of the furnace ranging from about 600°C to about 650°C and an outlet temperature ranging from about 800°C to about 1000°C.

[0022] The feed velocity through the coils ranges from about 300 to about 800 feet per second, based on the total flow of steam and hydrocarbons and also coil dimensions.

[0023] The residence time of the feed in the radiant section of the cracking coil generally ranges from about 30 to about 1000 milliseconds.

[0024] The effluent product gases issuing from the radiant zone are rapidly cooled to a temperature at which the cracking reactions substantially stop. This generally ranges from about 400°C to about 600°C.

[0025] Generally, the effluent from the pyrolysis reactor is directed to a quench boiler wherein the effluent is indirectly contacted with cooling water in cooling tubes. After traversing the cooling tubes, the water is removed from the quench boiler in a line and returned to a supply tank.

[0026] The gaseous effluent from the cracking reaction then passes through an olefins purification system. Typically the gaseous effluent is water washed, compressed, caustic washed, compressed and then dried. The dried effluent is chilled and passes through a deethanizer to separate the effluent into two component streams; a light stream (e.g., hydrogen, methane, acetylene, ethane and ethylene), and a heavy stream (e.g., propane, propylene and mixed C₄⁺ hydrocarbons). Then, the light product gases are compressed, and the acetylene components are removed by absorp-

tion or hydrogenated to ethylene in an acetylene hydrogenation reactor.

[0027] The effluent stream is cooled to a very low temperature typically from about -30°C to about -60°C and fed to a demethanizer to remove methane and hydrogen from the feed stream. The final treated effluent stream typically comprises from 70-99, preferably from 90-99 weight % of ethylene.

[0028] The effluent stream obtained from the olefins purification process may be employed as the feedstock for an ethylene polymerization or oligomerization process in accordance with the present invention. The feedstock for use in the polymerization process preferably contains at least about 75 weight % ethylene, more preferably at least about 85 weight % ethylene and most preferably from about 90 to 99 weight % ethylene.

[0029] The ethylene may be polymerized or oligomerized into polyethylene or alpha olefins either by solution, slurry or gas phase methods. Generally the pressure in the polymerization reactor for a solution process may exceed about 3,000 psi (20 MPa) (e.g. about 3,000 to 10,000 psi (20 MPa to 70 MPa), preferably from 3,000 to 5,000 psi (20 MPa to 35 MPa). This moderate pressure is necessary to maintain the monomers and comonomers in solution even at the solution's high reaction temperature.

[0030] In these processes ethylene is dissolved in a liquid hydrocarbyl medium (e.g. C₅₋₁₀ alkyl and/or an aromatic hydrocarbon). The solution is contacted/mixed with a catalyst. The catalyst may be a conventional Ziegler Natta type catalyst, a metallocene type catalyst used by Exxon, a constrained geometry catalyst used by Dow or it could contain novel ligands such as phosphinimine ligands. Depending on the temperature the process may be a slurry process (polymer precipitates from solution) as are disclosed for example in patents to Phillips (typically below about 100°C) or the polymer may remain in solution (temperature from 180°C to 300°C) as described in patents to, in the name of DuPont Canada, Novacor and Nova Chemicals Ltd.

[0031] The catalyst may also be Ni, Zr, Cr or Ti based oligomerization catalyst.

[0032] In the solution polymerization process the catalyst is deactivated and remains in the polymer. The polymer and solvent are then separated and the solvent is heated to remove residual unreacted feed (e.g., ethylene and ethane). The feed is then recycled to the cracker.

[0033] In the slurry polymerization process the polymer is separated from the diluent and the diluent is then heated to remove the unreacted feed. The polymerization may be a gas phase polymerization conducted at temperatures from about 80°C to 115°C at pressures from about atmospheric to 150 psig (gauge pressure of 1 MPa).

[0034] The current state of the art of gas phase polymerization process has low conversion per pass and inherently is not suitable for dilute ethylene utilization at this time. More advancements in catalyst technology and heat transfer might in future overcome this disadvantage.

[0035] In a further aspect of the present invention the ethylene from the cracker may be feed to an oligomerization unit. Typically these units condense ethylene into higher alpha olefins such as butene, hexene and octene although higher alpha olefins, up to about C₂₀, may be produced. Generally, in these processes, ethylene is contacted with a catalyst typically comprising of an aluminum alkyl (e.g. tri methyl aluminum or tri ethyl aluminum) or an aluminum complex of the formula (R⁴)₂AlO(R⁴AlO)_mAl(R⁴)₂ wherein each R⁴ is independently selected from the group consisting of C₁₋₂₀ hydrocarbyl radicals and m is from 0 to 50, preferably R⁴ is a C₁₋₄ alkyl radical and m is from 5 to 30. The ethylene alpha olefin are at least recycled through a reaction or chain growth zone to grow the alpha olefin (e.g. increase the length by 2 carbon atoms (1 ethylene add on) as a result there is generally a statistical distribution of alpha olefins in the resulting product. The product is generally distilled to separate different alpha olefins. Generally, the process is conducted at pressures from about 2,000 to 5,000 (13 MPa to 35 MPa), preferably 2,000 to 3,500 psig (13 MPa to 25 MPa) and temperatures from about 90°C to 180°C. Such processes are well known and described for example in U. S. Patent 4,935,569 issued June 19, 1990 assigned to Ethyl Corporation.

[0036] The ethylene stream from the cracker may also be fed to an oligomerization unit which uses transition metal complexes as catalysts and may also use alkylaluminum compounds of the formula AlR_xX_{3-x} as cocatalysts wherein R is a C₁₋₈, preferably C₁₋₄ alkyl radical, X is a halogen, preferably chlorine or bromine, and x is an integer from 1 to 3. Titanium, zirconium, hafnium, chromium, nickel or molybdenum could be used as active components of the complex catalysts. These processes require milder reaction conditions - pressures from 15 to 1500 psig (gauge pressures of 0.1 to 10.5 MPa) and temperatures from 0°C to 150°C. Such processes are known and described for example in "The Nickel-Complex Catalyzed Synthesis of α-Olefins" paper by Arno Behr and Wilhelm Keim in The Arabian Journal for Science and Engineering, Vol. 10, No. 4 or in the European Patent Application 241,596 published November 21, 1987 the texts of which are herein incorporated by reference.

[0037] The present invention will be more fully described in association with the drawings. Figures 1a and 1b are the simple mass balances generated by a computer program which accurately reflect commercial operations that compare the flow of materials. The calculations are based on a plant to produce 100,000 tons/yr. of ethylene going into a polyethylene unit. In the figure the bold numbers are tons of product.

[0038] Fresh feed stream (1) is introduced into the furnace in combination with dilution steam stream (3) and ethane recycle stream (9) respectively. The mass going through the furnace is therefore stream (2) = [(1)+(3)+(9)]. After cracking in the furnace and quenching, water is recovered and dilution stream is recycled.

[0039] The compressor which receives the cracked gases (stream 4) boosts the pressure of the stream before it goes to a deethanizer. From the deethanizer, C₃'s and heavier products are separated as stream (6) from the lighter fractions. The C₂'s and lighter materials (stream 5) enter the acetylene removal/conversion system and from there to the demethanizer. Off gases made up mainly of methane and hydrogen are removed as stream (8) while stream (7) in a conventional process goes to an ethane splitter. There ethane is separated from ethylene product (stream 10) while ethane from the stripper is recycled back to the furnace (stream 9). The figures illustrate the following improvements arising from the present invention as seen in Tables 1 to 3.

TABLE 1

Comparison Arising From Mass Balances		
Mass Flow	Invention (metric tons/yr)	Prior Art (metric tons/yr)
To Cracking Furnace	205,044	265,551
Load on Compressor	158,941	205,774
C3 + Products	11,677	11,192
Acetylene Reactor	147,265	195,551
Offgas	19,961	17,550
Load to Splitter	0	176,898
Ethane Recycle	26,800	76,901

[0040] In the process of the present invention illustrated in Figure 1b, a polyolefins or oligomerization unit serves as the separator, and the unreacted ethane is recycled back to the furnace. The advantages of this over the conventional method become obvious to anyone knowledgeable in the art, when one studies Tables 1 to 4, as follows:

- a smaller load for the furnace
- a smaller cracked gas compressor
- a smaller acetylene processing unit
- the absence of an ethane/ethylene splitter
- a greatly reduced recycle of ethane
- a small integrated ethylene/polyethylene unit
- reduced energy requirements
- lower operating costs

[0041] The capital cost for the process of this invention compared to the conventional process, for the same plant capacity, is lower.

[0042] Figures 2a and 2b show the heat balances for both the conventional and the new process. The heat loads are given in gigajoules per hour. The total energy requirements for the conventional system is 320.9 GJ/hr as opposed to 229.6 GJ/hr for the new process. Tables 2 to 4 show the Energy Requirements, Energy Consumption/Generation and Operating Cost respectively for the prior art versus the invention.

TABLE 2

Energy Requirements		
	Invention [GJ/hr.]	Prior-Art [GJ/hr.]
Furnace	159.1	198.3

[0043] The conditions for the simulation are as follows:

- Inlet pressure: around 1.97 kg/cm² A
- Internal Diameter: 0.038 M
- Coil Residence Time \approx 120 ms
- Dilution Steam Ratio (kg steam/kg ethane) = 0.3

[0044] The conventional runs were simulated for 65% ethane conversion in the furnace, while the new process runs were simulated for 88% ethane conversion.

Example 1:

[0045] Table 5 shows the effect of Coil Outlet Temperature on ethylene yield based on computer simulations of an ethylene cracker.

10 Claims

1. An integrated process for the cracking of a feedstock to produce ethylene and the subsequent polymerization or oligomerization of the ethylene, in the ethane/ethylene stream, without passing through an ethane splitter comprising in cooperating arrangement the steps of:
 - i) feeding a feedstock to a cracker operated at a maximum allowable tube wall temperature of from 1050°C to 1600°C;
 - ii) passing the resulting product through a separation step to remove hydrocarbon streams having a carbon content of 3 and greater;
 - iii) subjecting the resulting stream to a treatment to convert acetylene to ethylene;
 - iv) removing the methane and hydrogen from the resulting stream to produce a product having an ethylene content from 75 weight % to 95 weight %;
 - v) feeding the resulting stream to a polymerization or oligomerization process and polymerizing or oligomerizing the ethylene;
 - and
 - vi) separating the unpolymerized stream from the polymer and solvent, returning it to the cracker.
2. The process according to claim 1, wherein the oligomerization is a solution, slurry, or gas phase operated process.
3. The process according to claim 1 or claim 2, wherein the feedstock is ethane, naphtha or gas oil.
4. The process according to any one of claims 1 to 3, wherein the residence time in the cracker is in the range 30 to 1000 milliseconds.
5. The process according to any one of the preceding claims, wherein the furnace tubes in the cracker are austenitic stainless steel and the maximum allowable tube wall temperature is in the range 1050°C to 1250°C.
6. The process according to any one of the preceding claims, wherein the furnace tubes of the reactor are made of ceramic or high temperature alloy and the maximum allowable tube wall temperature is in the range 1200°C to 1600°C.
7. The process according to claim 6, wherein the furnace tubes are made of ceramic, the ceramic being silicon carbide and the maximum allowable tube wall temperature is in the range 1200°C to 1400°C.
8. The process according to any one of the preceding claims, wherein the ethylene content in the feed to the oligomerization or polymerization process is greater than 75 weight %.
9. The process according to any one of the preceding claims, wherein the polymerization or oligomerization process is a solution process operated at a pressure in the range 3,000 psi to 5,000 psi (20 MPa to 35 MPa).
10. The process according to any one of claims 1 to 8, wherein the polymerization or oligomerization process is a slurry process.
11. The process according to any one of claims 1 to 8, wherein the oligomerization process is a gas phase process.
12. The process according to any one of the preceding claims, wherein the conversion of ethylene to polyethylene is greater than 85%.

13. The process according to claim 12, wherein the conversion of ethylene to polyethylene is greater than 85% on a once through basis.
14. The process according to any one of the preceding claims, wherein the feed from the cracking process is fed to a polymerization process.
15. The process according to any one of claims 1 to 13, wherein the feed from the cracker is fed to an oligomerization unit.
16. The process according to claim 15, wherein the catalyst in the oligomerization unit comprises an alkylaluminum compound or a transition metal complex of titanium, zirconium, hafnium, chromium, nickel or molybdenum with or without an alkylaluminum compound.
17. The process according to claim 16, wherein the alkylaluminum compound is ethyl aluminum or tri methyl aluminum.
18. The process according to claim 16, wherein the alkylaluminum compound has the formula $(R^4)_2AlO(R^4AlO)_mAl(R^4)_2$ wherein each R^4 is one of the group consisting of C_{1-20} hydrocarbyl radicals and m is in the range 0 to 50.
19. The process according to claim 18 wherein R^4 is a C_{1-4} alkyl radical and m is in the range 5 to 30.
20. The process according to claim 16, wherein the alkylaluminum compound has the formula AlR_xX_{3-x} wherein R is a linear or branched alkyl radical comprising 2 to 8 carbon atoms, X is chlorine or bromine and x is equal to 1, 2 or 3.
